Visualizing Positional Uncertainties of Geometric Corrected Remote Sensing Images

Carlos Vieira *, Giuliano Marotta, Dalto Rodrigues and Rafael Andrade

Federal University of Viçosa – Civil Engineering Department – DEC
Surveying Engineering Sector, Viçosa – MG – Brazil CEP 36570-000

Abstract. A new method to evaluate and to visualize positional uncertainties that occur through the geometric correction process of remote sensing images is successfully presented. Five different transformation methods are described. Results show that the best RMS error was obtained by 3D the projective modified model and the worst one was obtained by the 2D affine model. The 3D projective model and 3D projective modified one were very similar in performance. These results also point out the importance in choose a better transformation model in order to perform the geometric corrections in remote sensed data and emphasize the importance of select a number of GCP spread all over the study area. Moreover, using the proposed positional error map, it is possible to evaluate every observation, with its precisions, offering high confidence in the transformed image coordinates. It is also important to mention that the use of the variance propagation rules allows analyzing the residual uncertainties of the transformation parameters spatially in the entire image.

Keywords: positional accuracy, error propagation, geometric correction, least mean square, visualizing uncertainty.

1. Introduction

High spatial resolution of orbital sensors provides greater facility on the collection of control points to perform the geometric correction of remote sensing images. However, it is important to be careful and precise during the process of obtain these reference coordinates, because inherent errors to the reference coordinates, as well as the processes of obtain them, can propagate uncertainty to derived products. Therefore, in order to evaluate the quality of these geometrically corrected images, there is a need to involve techniques that put in evidence the positional uncertainty on explicit and spatial form.

Thus, the objective of this article is to evaluate and to visualize uncertainties that occur through the geometric correction process of remote sensing images and its effect into the final coordinates of geometrically corrected images. Moreover, it is also noticed that knowing the positional coordinates, and its uncertainties, allows the analyst to determine the potentialities and applications of the geometrically corrected image, related to the positional aspect.

2. Material and Methods

2.1. Study Area

The study area is located in the southeast of Brazil, on the Minas Gerais State, at the Campus of the Federal University of Viçosa (Figure 1). The region has a dramatic landscape, with mountains all over the region.

2.2. Material
It was used a QuickBird image in order to carry out the experiments, with spatial and radiometric resolution of 0.60m and 11 bits respectively. It was also used the system ERDAS Imagine 8.3.1 version, for visual control points extractions and visualizations.

Three Ashtech Promark II GPS receivers were used to collect Ground Control Points (GCP) and the Trimble Geomatics Office 1.63 software was also used to process and adjust the coordinates.

It was collected 13 very well defined and distributed ground control points and their homologous ones on the Quickbird image. Figure 2 shows the ground control points and their location in relation to the VICO GPS reference station, which belongs to the Brazilian Geodesic Network of Continuous Monitoring (RBMC).

2.3. Methods
The firs step was an identification of control features, and then perform the extraction of the coordinates in a Quickbird image and the determination of their homologous reference coordinates on the ground, using a GPS Receiver (Arruda, 2002).
A topographical polygon was implanted on the field, with many vertices. This polygon was linked to three known GPS points of the Brazilian National Grid, covering 1,5 km square inside the study area at the campus of the Federal University of Viçosa.

The polygon computation was carried out using the parametric model of the Least Mean Squares (LMS) method that provided the positional covariance for every polygon vertices (i.e., GCP). This process allowed to get know, the positional uncertainties associates to all the used GCP, which is needed to perform the orbital image geometric correction (Baltsavis et al., 2001).

Using the reference coordinates and their homologous image extracted coordinates were calculated the transformation parameters, using two different transformation models: affine and projective ones and their variants for two dimensions (2D) and three dimension (3D) transformations. Such procedure allows the association of a positional uncertainty of the image corrected as a function of the inherent uncertainties from the reference coordinates. In addition, these uncertainties had been propagated through the transformation parameters to the rectified image coordinates.

Transformations models are mathematical equations used to transform coordinates between projection systems. The affine and projective transformations models and their variants will be presented in the following sub-sections.

### 2.3.1. The Affine Models

The affine model for 2D uses six parameters to model transformations between projections systems (Fraser 2004). These parameters are: two translation parameters ($\Delta C, \Delta L$); one rotation parameter ($k$), two scale factors ($\lambda_u, \lambda_v$) and a factor of non-orthogonality between axes ($\varepsilon_{xy}$), which are presented in the following equations:

\[
\begin{align*}
C &= \lambda_u X \cdot \cos k - \lambda_v Y \cdot \sin k + \Delta C \\
L &= \lambda_u X \cdot \sin (k + \varepsilon_{xy}) + \lambda_v Y \cdot \cos (k + \varepsilon_{xy}) + \Delta L
\end{align*}
\]

where $X$ and $Y$ are the reference coordinates and $C$ (column) and $L$ (line) are their homologue image coordinates.

The affine model can be written using a matrices notation:

\[
\begin{bmatrix}
C \\
L
\end{bmatrix} = \begin{bmatrix}
a_1 & a_2 & a_3 \\
a_4 & a_5 & a_6
\end{bmatrix} \begin{bmatrix}
X \\
Y
\end{bmatrix} + \begin{bmatrix}
a_7 \\
a_8
\end{bmatrix}
\]

\[
\begin{bmatrix}
C \\
L \\
Z
\end{bmatrix} = \begin{bmatrix}
a_1 & a_2 & a_3 & a_4 \\
a_5 & a_6 & a_7 & a_8 \\
a_9 & a_{10} & a_{11} & a_{12}
\end{bmatrix} \begin{bmatrix}
X \\
Y \\
Z
\end{bmatrix}
\]

where onde : $C, L, z$ – represent the point coordinates on the image space; and $X, Y, Z$ – represent the point coordinates on the object space; and, $a_1...a_{12}$ – represent the transformation parameters.

### 2.3.2. The Projective Models

The projective models represent a simplification of the co-linearity model (Mitishita et al., 2003). According to Andrade (2003) a bi-dimensional projective coordinate transformation requires eight parameters and the utilization of this transformation model is appropriated when a bi-dimensional coordinate system is projected to other one that is no parallel. Summing up, the projective model includes non parallelism between the Cartesian systems.
It is necessary to not consider the altitude of the points on the object space \( Z_P = 0 \), and after the inherent simplifications of the original projective model, the following equations are derived for the 2D projective model:

\[
C = \frac{a_1X + a_2Y + a_3}{a_7X + a_8Y + 1} \tag{5}
\]

\[
L = \frac{a_4X + a_5Y + a_6}{a_7X + a_8Y + 1} \tag{6}
\]

where: \( C, L \) – represent the point coordinates on the image space \( (C_p, L_p) \); \( X, Y \) – represent the point coordinates on the object space \( (X_p, Y_p) \); \( a_1...a_8 \) – represent the transformation parameters.

Similarly, the 3D projective transformation model also performs inherent simplifications on the original projective model, however, this model considers the altitude value \( Z_P \neq 0 \) in order to determine the parameters and on the coordinate transformation between non orthogonal systems, as follow:

\[
C = \frac{a_1X + a_2Y + a_3Z + a_4}{a_9X + a_{10}Y + a_{11}Z + 1} \tag{7}
\]

\[
L = \frac{a_5X + a_6Y + a_7Z + a_8}{a_9X + a_{10}Y + a_{11}Z + 1} \tag{8}
\]

where: \( C, L \) – represent the point coordinates on the image space \( (C_p, L_p) \); \( X, Y, Z \) – represent the point coordinates on the object space \( (X_p, Y_p, Z_p) \); \( a_1...a_{11} \) – represent the transformation parameters.

There is also an alternative modified model, named by Wang (1999) and Valadan (2003) as Calibration Direct Linear Transformation (SDLT), which consists in an addition of one more parameter \( a_{12} \) on the Equation (8), referring to the 3D projective model. This 3D modified projective model defines 14 parameters that promote the relation between the 2D and 3D space, as following:

\[
C = \frac{a_{11}X + a_{2}Y + a_{3}Z + a_{4}}{a_{9}X + a_{10}Y + a_{11}Z + 1} \tag{9}
\]

\[
L = \frac{a_{5}X + a_{6}Y + a_{7}Z + a_{8}}{a_{9}X + a_{10}Y + a_{11}Z + 1} + a_{12}CL \tag{10}
\]

According to Wang (1999) this 3D modified projective model represents a linear transformation process between image and ground coordinates, with an additional correction for the image coordinates (parameter \( a_{12} \)), in order do adjust systematic errors. Using this model, there is no need for the use of interior orientation parameters, neither for use of approximated exterior orientation parameters (ephemerid information).

The determination of these parameters, for all these transformations models, used the parametric Least Mean Square (LMS).

### 2.3.3. Parameters’ Determination

The determination of these parameters, for all these transformations models, used the parametric Least Mean Square (LMS) method, in which the observations \( L_b \) plus the observation residuals \( V \) must be equal to the function \( F(X_a) \) of the mathematical model used (Gemael, 1994), in relation to adjusted parameters:

\[
L_b + V = F(X_a) \tag{11}
\]

A stochastic model was set up based on variances of the screen coordinates observed \( C_{lb} \). These variances were arbitrary chosen and all of them had the same standard deviations, as following:

\[
C_{lb} = \text{diag} \left[ \sigma_{c_1}^2 \sigma_{c_1}^2 \ldots \sigma_{c_N}^2 \sigma_{l_N}^2 \right] \tag{12}
\]
This arbitrary procedure of have chosen the variances \textit{a priori} is utilized for the computations of the weights on the observations, which is recomputed due to a variance in the \textit{a posteriori} adjustment, in order to adequate to the adjusted parameters.

After the computation of parameters and weight fitness, it is computed the variance-covariance matrix (VCM) of the observed values and of the adjusted parameters, which is generated by:

\[
C_{\text{PAR}} = \hat{\sigma}^2_{\hat{\sigma}}(A^T P A)^{-1}
\]  

Using these adjusted parameters and the extracted image coordinates (C and L), it is possible perform the transformation between systems through the inverse model and obtain the coordinates (X, Y and Z) for every pixel of the image in the geodesic system.

2.3.4. Models Evaluations and Positional Error Map Generation

The precision of the adjustment model was performed using both: the RMS error analysis and the verification of the \textit{a posteriori sigma 0}, which was evaluated through the \(X^2\) statistical test, using a significance level of 0.05, for each transformation model. Thus, to perform these computations, it is necessary to multiply the \textit{a posteriori} reference variance by the freedom degree and compare it with the tabled value. If the computed value is inside of a tabled interval, the assumed hypothesis is accepted, in which the \textit{a priori} reference variance is statistically equal to the \textit{a posteriori} reference variance.

In order to compute the \textit{a posteriori} adjustment variance uses the equations:

\[
\hat{\sigma}^2_0 = \frac{V^T P V}{GL}
\]  

\[
P = \sigma^2_0 C^{-1}_{\text{LL}}
\]

where P is the observations residuals and GL is the freedom degree (the difference between the number of observations and the number of parameters).

After the acceptance of the precision test, the uncertainties of the transformation parameters and of the reference coordinates were propagated into the geometrically corrected image, and then, RMS errors were generated for every pixel in the image. Thus, a position error map could be generated, using the individual RMS, in meters, for each pixel of the image.

C = Column, L = Line, h = altitude.

Table 1 presents the set of 13 coordinates, which were collected directly from the satellite image. It is observed that the collection error for each coordinate was assumed to be 0.5 pixels for every collected point and the altitudes were not collected.

In addition, it was performed a field collection of homologous points, identified from the image, using GPS receivers. The data were processed using the RBMC VICO as reference GPS station, and results are presented on the Table 2.
The next step was to perform the observations adjustment using the *Least Mean Square* method for each transformation model and then it was evaluated the precision of every model through the RMS error and the verification of the *a posteriori* sigma 0 analysis (Marotta and Vieira, 2005).

X = Este (E), Y = Norte (N), h = geometric altitude.

The global RMS error for each transformation model is presented in Figure 3. It is shown that the best RMS error was obtained by the 3D projective modified model (0.55 pixels) and the worst one was obtained by the 2D affine model (2.09 pixels), as expected. The 3D projective model presented very similar RMS error (0.60 pixels). These results point out the importance of choose a better transformation model in order to perform the geometric corrections in remote sensed data.

Figure 4 show a graph with the *a posteriori* variances behavior for each transformation model after the LMS adjustment. The results were very consistent with the RMS error analysis. Observing the results, it is possible to conclude that both the 3D projective and the 3D projective modified models obtained the best adjustment results, compared to the other ones. Moreover, it is observed that both models presented very similar values too.
Although these measures indicate the best and the worst transformation model to be used, they are non-spatial statistic measures; therefore, they do not consider the positional aspect of the uncertainty. In order to perform a spatial evaluation of uncertainty it was proposed a method, in which is performed variances propagation through the inverse transformation models to obtain the RMS errors, from residual, for every image pixel, bringing adjusted parameters uncertainty into the transformed coordinates.

Figure 5: The spatialisation of the errors for each transformation model. Thus, after the spatialization uncertainty process, it is possible to evaluate areas where the positional accuracy is less precise than other one. The analyst could consider the possibility of densification of control points in this area in order to improve the positional accuracy and a better adjustment of the transformation model.
Although the non spatial statistic measures (RMS error and sigma a posteriori) point out the 3D projective modified model as the best one, through the propagation of the uncertainty, it is possible to conclude that the 3D projective model presented a better result.

4. Conclusion

After perform the experiments, it is conclude that the best RMS error was obtained by the 3D projective modified model and the worst one was obtained by the 2D affine model. The 3D projective model and 3D projective modified one were very similar in performance. These results point out the importance in choose a better transformation model in order to perform the geometric corrections in remote sensed data. In addition results show that the uncertainties increases as pixels get far away from the support polygon (i.e., GCP), which emphasize the importance of select a number of GCP spread all over the study area. Moreover, using the proposed positional error map, it is possible to evaluate every observation, with its precisions, offering high confidence in the transformed image coordinates. It is also important to mention that the use of the variance propagation rules allows analyzing the residual uncertainties of the transformation parameters spatially in the entire image. Research needs to be developed in order to verify the potential use of these tools for uncertainties visualization of geometrically corrected remote sensing images. Considering the positional error map the 3D projective model presented a better transformation result.
